Optimizing stomatal traits to enhance biomass under fluctuating light

May 15, 2025

This study found that cotton planted under high density responded faster to fluctuating light conditions. Photo courtesy of Zhangying Lei.

Plants under natural environments constantly experience fluctuating light, and the speed of their response to it directly affects photosynthetic efficiency and yield. Therefore, improving fluctuating light use efficiency is a challenge for achieving high-yield agriculture. However, the effects of planting density on the frequency characteristics of fluctuating light and its regulatory mechanisms on stomatal behavior have not been fully explored.

To fill this knowledge gap, researchers at Northwest A&F University in Xianyang, China investigated stomatal anatomy and response rate and biomass of cotton (*Gossypium hirsutum* L.) planted at low, medium, and high densities. The results showed that higher planting density significantly increased the frequency of light fluctuations at the lower cotton canopy. Under high density conditions, stomata on the underside leaf surface became smaller and denser, enabling faster response to light fluctuations. This enhanced photosynthetic induction capacity and led to higher biomass accumulation.

These findings suggest that plants can optimize stomatal traits to increase biomass under fluctuating light. Therefore, selecting cotton varieties with rapid stomatal response rate may provide a promising strategy for improving agricultural productivity under dynamic light conditions.
